Project 1

Introduction

The Benchmark

In the following we use the model of a pendulum attached to a rod which is elastic in the radial direction as described in Task 1. The situation is depicted in figure 1.

This problem leads to the formulation as an ODE

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix}' = \begin{bmatrix} y_3 \\ y_4 \\ -y_1 \lambda(y_1, y_2) \\ -y_2 \lambda(y_1, y_2) - 1 \end{bmatrix}$$

with

$$\lambda(y_1, y_2) = k \frac{\|(y_1, y_2)\| - 1}{\|(y_1, y_2)\|}.$$

The plot of a numerical solution to this problem for k = 1 can be seen in figures 2 3 and 4.

We can calculate the potential, kinetic and approximate the elastic energy with the formulas

$$E_{\text{pot}} = 1 + y_2$$
 $E_{\text{kin}} = \frac{\|(y_3, y_4)\|^2}{2}$

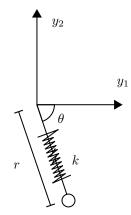

Figure 1: The pendulum

$$E_{\text{elast}} = k \frac{(\|(y_1, y_2)\| - 1)^2}{2}$$
.

Adding these up we get the approximate total energy

$$E_{\text{tot}} = E_{\text{pot}} + E_{\text{kin}} + E_{\text{elast}}$$
.

We expect the approximate total energy to be constant which indeed can be seen in Figure 5 for that previously calculated numerical solution. Because of this property we can use the relative variation of the approximate total energy as an index to measure the stability of the method. We specifically implement

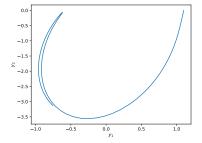

Figure 2: State in dependence of time.

Figure 3: Path traced out by pendulum.

In the ideal world this index almost vanishes.

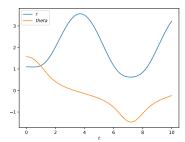

Figure 4: Polar coordinates.

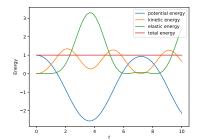

Figure 5: Energy plot

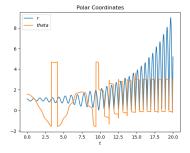

Testing Explicit Methods

For linear problems, explicit methods present a much reduced stability region which dictates the possible step sizes for that specific method. For the problem of the elastic pendulum, approximated by explicit methods, when the value of k is increased we are expected to see the approximation blow up showing oscillations of unbounded amplitude. This unstable behavior will be attenuated by reducing the value of the step h.

The problem was simulated using Explicit Euler and RK4. All the experiments in this section, if not otherwise stated, take as initial value $y_0 = [1.1, 0, 0, 0]$ and have [0, 20] for domain. The graphs are presented in polar coordinates where r

refers to the length of the spring and θ refers to the angle conformed between the pendulum and the vertical axis.

It can be observed that for a step size of h=0.01 Explicit Eurler (Figure 6) already shows instability for values of k=50 while RK4 (Figure 7) with that same step size remains stable for values up to k=3000.

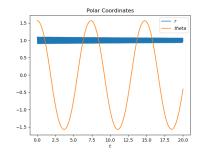

Figure 6: Explicit Euler h = 0.01k = 50

Figure 7: RK4 h = 0.01 k = 3000

For Explicit Euler (Figure 8), by keeping the value of k constant and reducing the step size by a decimal place we can see how the instability is attenuated presenting a similar amplitude over time. It takes a much larger step size and spring constant for RK4 to become unstable (Figure 9), once unstabilized it's growth is much more rapid than Explicit Euler's and it does so without oscillating.

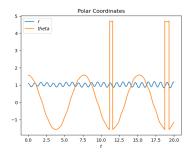

Figure 8: Explicit Euler h = 0.001 k = 50

Figure 9: RK4 h = 0.1 k = 975

It is interesting to observe that the oscillation of the spring is rapidly dumped when using RK4 (Figure 10), a behavior similar to that presented by implicit methods. This behavior cannot be observed in the other explicit methods.

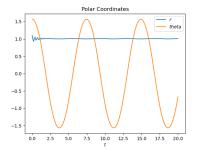

Figure 10: RK4 h = 0.1 k = 300

Testing Implicit Methods

Opposite to the case of explicit methods, for linear problems implicit methods count with an extensive stability region which doesn't make their stability dependent on the value of the step k. The problem was simulated using Implicit Euler, BDF2 with Fixed Point as corrector and BDFk with Newton as corrector for k between 1 and 4. All the following experiments take as initial value $y_0 = [1.1, 0, 0, 0]$ and have [0, 20] for time domain. It is interesting to see how the oscillation of the spring decays for implicit methods. This decay can be attenuated by reducing the step size or accelerated by increasing the value of the spring constant.

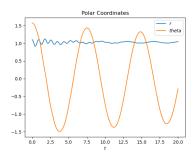

Figure 11: Implicit Euler h = 0.01 k = 50

The method BDFk with Newton presents a decay in the spring oscillation as the other methods do. However, it also shows decay of the pendulum oscillation which cannot be observed in the other implicit methods. To better observe this decay (Figure 14 and Figure 15) the domain is increased to [0, 100].

It is interesting to see how the relation between the speed of decay of the spring oscillation in inversely proportional to the size of the stability region of the methods tested.

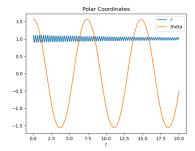

Figure 12: BDF2-Fixed Point h = 0.001 k = 500

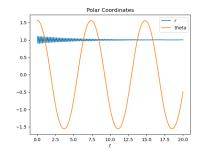

Figure 13: BDF2-Fixed Point $h = 0.01 \ k = 1000$

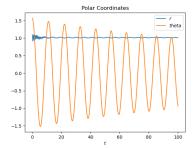

Figure 14: BDF2-Newton h=0.01 k=100

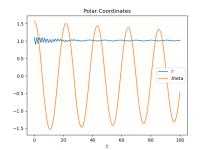

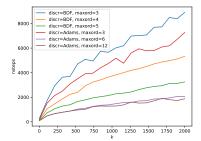

Figure 15: BDF4-Newton h = 0.01k = 100

Testing CVODE

A first test series

In the first specific test of CVODE we solve our toy problem for increasing k. Here we switch between the BDF and Adam-Moultons discretisation method. We also vary the maxorder parameter for both methods. A higher k reflects a problem which is more stiff. As a stiff problem requires smaller steps the number of steps nsteps increases as k increases which can be seen in figure 16. As the number of function evaluations per stepsize nfcns/nsteps hovers slightly above 1 for all methods (c.f. figure 18) the number of function evaluations increase analogously to nsteps with k as can be seen in figure 17. There is however a difference in how many steps each method needs. The BDF-method requires in general more steps than the Adams-Moulton method. And the general trend is that the number of steps increases as maxord is reduced.

From figure 19 it can be seen that the number of jacobian evaluations stays roughly constant and happens roughly every 5th step. The number nerrfails/steps stays roughly constant in dependence of k though the general tendency

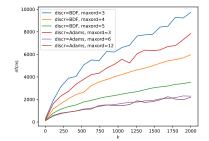

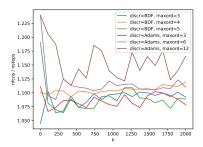

Figure 16: **nsteps** in relation to the parameter k.

Figure 17: **nfuncs** in relation to the parameter k.

is that it is smaller the lower maxord is set. This makes sense because a lower maxord means there are fewer possibilities for the method order and hence fewer changes of order. In figure 21 we see a difference in how much the methods obey the principles of energy conservation. One can see that for growing k the result tends to be further away from physical reality. Once again the methods with higher maxord do better with the exception of the BDF method where for some reason a maxord of 4 performs best.

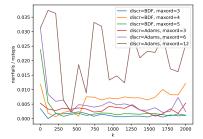

Figure 18: nfcns/nsteps in relation to the parameter k.

Figure 19: njacs/nsteps in relation to the parameter k.

This test confirms once again that a stiffer Problem needs more function evaluations in CVODE. Perhaps surprisingly the Adams-Moulton-method seems to perform better on this problem. This experiment also highlights that a lower maxord parameter tends to be more computationally expensive though it reduces the number of error test failures nerrfails.

Testing the parameter rtol

We now test the influence of the parameter rtol on the methods BDF and Adams-Moulton. For this we set $k = 10^3$ and keep all other parameters on their

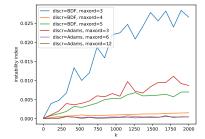

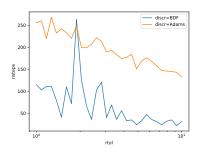

Figure 20: nerrfails/nsteps in relation to the parameter k.

Figure 21: instability index in relation to the parameter k.

default values. The results can be seen in figures 22 to 26. We note that as rtol increases the number of steps decreases (c.f. figure 22). If one compares figures the instability index for $k \approx 10^3$ in figure 21 with the instability index in figure 26 one sees that changing the rtol parameter from the default makes the result significantly worse in terms of energy conservation.

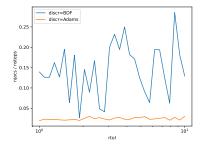

Figure 22: nsteps in relation to the parameter rtol.

Figure 23: nfcns/nsteps in relation to the parameter rtol.

Testing the parameter atol

If we test the atol parameter on the Adams and Newton method analogously to the test of the rtol parameter we once again get an instability index that is significantly above the value for the method in which we did not specify this value as can be seen in Figure 27. In either case we observe that fixing the tolerance seems to come at the cost of energy conversation as is dramatically visualised in Figures 28 and 29.

All in all we see that none of the (admittedly crude) tweaking of the parameters improved the performance of CVODE. To the contrary, most changes worsened the performance. The choice of the discretisation method on the other

hand did make a big difference and the performance for solving the toy problem could be improved by switching from the default BDF method.

Project 2

In this project we used the implementation of the seven body mechanism as described in [3] to test Assimulo's implicit solvers. The problem formulation leads to an index 3 problem of the form

$$M(q) q'' = f(q, q') - G(q)^{\top} \lambda \tag{1}$$

$$0 = g(q) \tag{2}$$

where $q \in \mathbb{R}^7$, $\lambda \in \mathbb{R}^6$ and G = Dg. If we differentiate condition (2) we obtain the index 2 condition

$$0 = G(q) q'$$

and differentiating this again we obtain the index 1 formulation

$$0 = \partial_q^2 g(q) (q', q') + G(q) q''.$$

Note that condition (??) and (1) can be uniquely solved for q'' and λ and we then obtain an ODE in the explicit formulation. For the implementation we rewrite this second order system as a first order system by the usual trick of introducing the variable v=q' so that in the implicit formulation the problem depends on the variable

$$y = \begin{bmatrix} q \\ v \\ \lambda \end{bmatrix}$$

A plot of the solution of the index 1 formulation can be seen in Figures 30 to 32.

A comparison of the index 1, 2 and 3 formulations

We now would like to compare the solutions of the various formulations. To calculate the solutions we used the IDA solver (TODO: hyperlink). However, to get the problem to run we set the atol parameter to the large number 1E5 and the algvar parameter to False for the algebraic variable λ and for v. These settings remain unchainged and in the following we only vary the index of the

Figure 30: The angles of the solution to the index 2 problem.

Figure 31: The angle speed of the solution to the index 2 problem.

Figure 32: The Lagrange parameter of the solution to the index 2 problem.

problem. We can see in the figures 33 to 35 the difference of the index 1 solution subtraced from the index 3 solution. In the figures 36 to 38 we see the index 2 solution subtracted from the index 3 solution. As expected we see that the difference the solutions grows as time progresses.

Rather unexpectedly however the difference of the index 1 to the index 3 solution is in general greater than the difference of the index 2 to the index 3 solutions. Also unexpectedly these differences are noticable in the plots of the Lagrange parameter λ as shown in figures 39, 40 and 32. Here we see that the solution becomes increasingly rough as the index increases.

The performance of the IDA solver for the various indexes can be seen in figures 41 to 44. We see figure 41 that the number of steps of the solver increases with the index. As the number of function evaluations per step stays roughly constant by figure 42 this means that the number of function evaluations increases with the index. One other other notable statistic regards the number of error test failures for the different problems which can be seen in figure 44 where we see a larger difference between the problems though this is probably not statistically significant as the total number of error test failures is approximately a dozen.

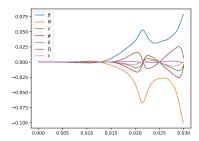

Figure 33: The difference of angles of the index 1 and the index 3 solution.

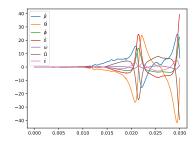

Figure 34: The difference in angle speeds of the index 1 and the index 3 solution.

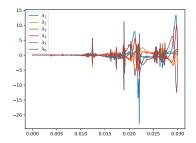

Figure 35: The difference of lambdas of the index 1 and the index 3 solution.

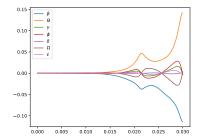

Figure 36: The difference of angles of the index 2 and the index 3 solution.

Dependence on the parameters alguar and atol

As previously indicated the IDA solver will throw an error

```
assimulo.solvers.sundials.IDAError: 'Convergence test failures occurred too many times during one internal time step or minimum step size was reached. At time 0 .000000.'
```

This can be resolved by declaring the entries of y corresponding to v and or λ to be algebraic variables with the parameter alguar and to set the parameter atol to a large variable. In the following we would like to check how these parameters impact the performance of the solver in the case of the index 1 formulation. For this we denote by alguar_v and alguar_lambda the value of the alguar parameter for v and λ . The default value of alguar is set to True. Analogously we denote the components of atol corresponding to v and λ with atol_v and atol_lambda and set the default value to 1E-6. We now run a

Figure 39: The Lagrange parameter of the index 2 problem.

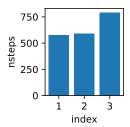

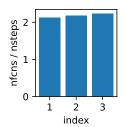

Figure 40: The Lagrange parameter of the index 3 problem.

series of 5 experiments as depicted in table 45.

As all experiments deliver more or less the same result we will be comparing the statistics of IDA as depicted in figures 46 to 51. Once again we observe in figure 49 that the total number of function evaluations is roughly proportional to the number of steps needed. Here experiments 1 and 4 stick out for requiring comparatively more function evaluations per step. However in figure 46 we see that these are also precisely the experiments in which the total number of steps taken is by far the least. Experiments 1 and 4 are also precisely those experiments that have the most stringent requirements on the v part of y. Both have set $atol_v=1E-6$ and declare v to not be an algebraic variable. We see in figures 48 and 51 that experiment 0 is an outlier in requiring comparitively many jacobian evaluations and having relatively few error test failures.
